- Goal
- What is Quantifier Elimination?
- What is Cylindrical Algebraic Decomposition?
- Weaponry: Python, Sympy, Github

Quantifier elimination

A quantifier-free formula is an expression consisting of

- Polynomial equations: $f(x) = 0$
- Inequalities: $f(x) \leq 0$
- "And" operator: \wedge
- "Or" operator: \vee
- "Implies" operator: \implies .

No variable is quantified by \forall nor \exists .

Theorem (Tarski-Seidenberg)

For every first-order formula over the real field there exists an equivalent quantifier-free formula and an explicit algorithm to compute this quantifier-free formula.

Cylindrical Algebraic Decomposition

- A CAD is a partition of \mathbb{R}^n into cylindrical cells, over which polynomials have constant signs.
- A cell is cylindrical if it has the form $S \times \mathbb{R}^k$
- A sample point per cell can be used to determine the sign of the polynomials in the cell.
- The CAD associated to a formula depends only on its quantifier-free part. We can use the CAD to evaluate its truth value, and to perform quantifier elimination.

1 Projection phase

We compute successive sets of polynomials in $n - 1, n - 2, \dots, 1$ variables. The main idea is, given an input set of polynomials, to compute at each step a new set of polynomials obtained by eliminating one variable at a time.

2 Lifting phase

We construct a decomposition of \mathbb{R} , at the lowest level of projection, after all but one variable have been eliminated.

This decomposition of \mathbb{R} is extended to a decomposition of \mathbb{R}^n .

3 Optionally, formula construction

- 8 QA

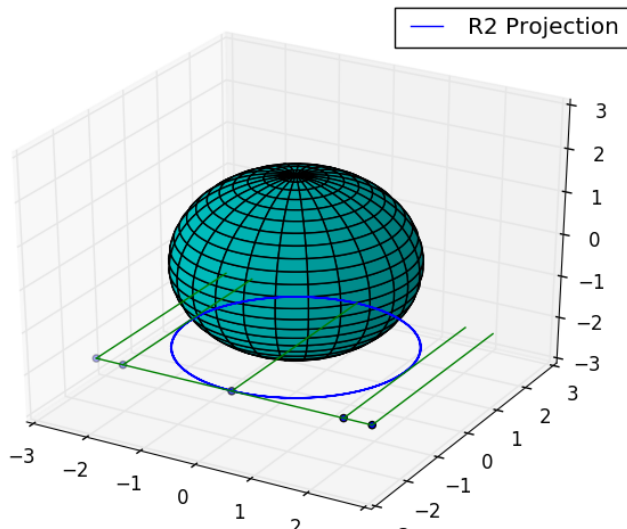

What have we accomplished?

- We learned python and how to use github.
- We made a full implementation of cylindrical algebraic decomposition such that:
 - The input is a set of polynomials that represent a region of the space. This polynomials are operated by the *Projection* part.
 - *Projection* does the cylindrical projection of the polynomials and makes a projection factor set.
 - Now the *Lifting* part of the code operates the projection factor set and makes the final decomposition.
 - That's our output, a cad that contains all the cells of the region.

Example 1: the sphere

Example 1: the sphere

Projection

- Input: $A = \{ \text{Poly}(x^2 + y^2 + z^2 - 4) \}$
- Output:
 - $A = \{ \text{Poly}(x^2 + y^2 + z^2 - 4) \}$
 - $\text{PROJ}(A) = \{ \text{Poly}(x^2 + y^2 - 4) \}$
 - $\text{PROJ}^2(A) = \{ \text{Poly}(x + 2), \text{Poly}(x - 2) \}$

Extension

- 6 Left to do
- 7 Behind the scenes
- 8 QA

Falls and comebacks

Projection

- Different definitions of the same function
- Special cases
- Iterating the projection function
- Different process described in different references

Falls and comebacks

Lifting

- The issue with eval function.
- Compute with algebraic numbers
- Learn algebra.
- Making tests.

Computing with algebraic numbers

Lifting

- The issue with eval function.
 - Symbolic method to find roots of polynomials: *only for rational coefficients*
- Computing with algebraic numbers
 - We represent an algebraic number with a polynomial and an interval
 - Operations on algebraic numbers become operations with polynomials

Algorithm

IN: Polynomial with *algebraic* coefficients with roots $\{\alpha_i\}$

OUT: A polynomial with *rational* coefficients with $\{\alpha_i\}$ among its roots

Table of Contents

- 3 Example 1: the sphere
- 4 Example 2: a paraboloid and a cylinder
- 5 Falls and comebacks
- 6 Left to do**
- 7 Behind the scenes
- 8 QA

- Optimization of the algorithm
- Refine the code to handle every case correctly
- Adapt code format to Python and Sympy standards
- Implement the quantifier elimination using the cad.

Theorem

Let \mathcal{D} be a domain and $0 \leq j \leq \min(p, q)$ if $p \neq q$ (resp. $0 \leq j \leq p - 1$ if $p = q$). Then $\deg(\gcd(P, Q)) \geq j$ if and only if

$$sRes_0(P, Q) = \cdots = sRes_{j-1}(P, Q) = 0$$
